

Deployment Manual

Page 1: Overview

This manual describes how to deploy internal applications maintained by the Engineering team, including Project Alpha, using the standard company deployment pipeline.

Before deploying Project Alpha, ensure the following prerequisites are installed on the target machine: Docker, Python 3.11, and Git. The deployment machine must also have at least 4GB of RAM available.

Project Alpha deployment requires the following production environment variables to be set: DATABASE_URL, SECRET_KEY, and REDIS_URL. These values must be provided through the secrets manager, never committed to source control.

To deploy Project Alpha: 1) Pull the latest release tag from the repository. 2) Build the Docker image using the provided Dockerfile. 3) Run database migrations. 4) Start the container using the production docker-compose file. 5) Verify the health check endpoint returns status 200.

If a deployment fails, roll back by redeploying the previous stable image tag and re-running the database migration rollback script. Notify the on-call engineer before performing a rollback in production.
